Abstract: - The IETF standard Mobile IP protocol is modified with IP security (IPSec) primitives, which control the packet flow from a mobile host through multiple security gateways. In addition, IPSec uses strong cryptographic authentication and encryption algorithms to protect the integrity and confidentiality of IP traffic. In this paper, we proposed a key management algorithm for Mobile IP networks based on IPSec. The proposed scheme includes two parts: a wired network and a wireless network. In the wired network part, the proposed scheme produce two keys in each security gateway, transfers a packet with an encrypted key and receives a packet with a decrypted key. In the wireless network part, we use AH to arrive at wireless segment packet security. By the proposed scheme, we can enhance the security of Mobile IP networks.

Key-Words: - Key management, IPSec, Mobile IP, Network security, Private key, Public key.

1 Introduction

The Internet, as well as most packet-switching networks, is based on the Internet protocol (IP). However, IP is inherently insecure. IP packets can be easily captured and can be modified and replaced in transit without the destination hosts being able to detect the modifications.

In the wireless networks (for example, Mobile IP, GSM and 3G), the wireless link is more vulnerable to the attacks, and the mobile devices (for example, notebook, PDA or mobile phone) are computing-capacity-limited and power-limited. These characteristics raise new challenges in designing the authentication scheme for wireless network [5]. Anonymity and un-trace ability is to protect the privacy of the identity of the sender.

IP mobility working on OSI layer 3 [1] is intended to provide Internet connectivity to mobile hosts when they are away from their home network and on a visiting network. The Internet Engineer Task Force (IETF) formed the IETF Mobile Working Group to draw up a standard of mobility support for IPv4, called Mobile IP [12]. IPSec provides connectionless data integrity, authentication, data confidentiality, anti-replay protection, data origin authentication, and limited traffic flow confidentiality. In [4], Johnson et al. proposed a security support in Mobile IP networks. Mobility has become the most imperative demand in recent spreading networking systems. For IPSec-based VPN users, Mobile IP developed by IETF is considered as the best solution for mobility management protocols [16].

In this paper, we proposed a new scheme to solve security problems in a Mobile IP environment. The proposed architecture is based on the IPSec-based VPN proposed by the IETF for mobile users. For IPSec-based VPN users, Mobile IP developed by the IETF is considered as the best solution for mobility management protocols. The proposed scheme consists of two parts: a wired network and a wireless network. In both networks, we use IPSec to enhance the security of our scheme. IPSec offers these services at the network layer, the layer in the TCP/IP protocol stack that contains the IP protocol. We change the way of one key in tradition as the method of two keys. In Mobile IP environment the agent that the packet must pass by is too many. So that very easy were invaded by the hacker or the password is cracked. Two keys absolutely can increase the safety.

The rest of the paper is organized as follows. In Section 2, we give an overview of Mobile IP and IPSec. We present the proposed IPSec-based key management algorithm for Mobile IP networks in Section 3. In Section 4, we compare IPSec-based Mobile IP with traditional Mobile IP. We give the conclusions in Section 5.

2 Overview of Mobile IP and IP Security (IPSec)

In this section, we give an overview of the Mobile IP and IP security protocol and describe them in some detail.

2.1 Main Component of Mobile IP

The basic concept of Mobile IP is as follows. Each MN must have a home address in its home network. When visiting any network away from home, each MN gets a temporary local address, called care-of address (CoA) [15]. On the visited network, the MN registers with its home agent so that the MN's current IP address can be tracked. Based on this concept, the functional components of Mobile IP are as follows: mobile node (MN), home agent (HA), foreign agent (FA), and correspondent node (CN) [15].

2.2 Basic Operations of Mobile IP

Fig. 1 shows the operations of the Mobile IP protocol [13]. With Mobile IP, a mobile node (MN) has a home agent (HA) that is a router attached to the network to which the node belongs. When the HA is out of range, the MN can connect to a foreign agent (FA) that communicates with the HA to help keep track of the MN. The MN must then be able to have an IP address that associates it with its attachment to a particular network. The FA assigns a care-of address (CoA) that is used for communicating with the MN while the MN is on the visited network. The MN can send and receive packets from any type of node on the network. When communication is taking place between an MN and another node, the node that the MN is communicating with is referred to as the correspondent node (CN).

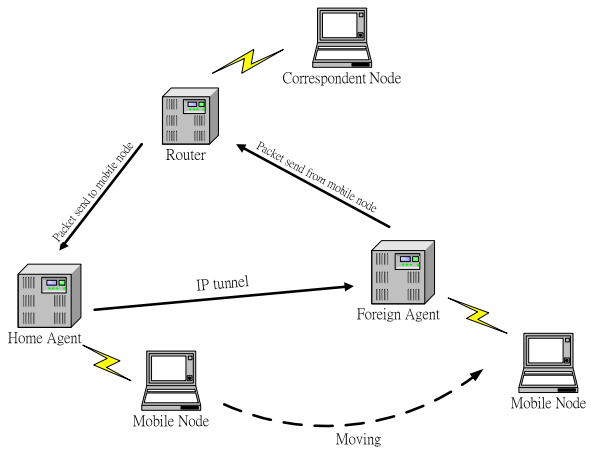

Fig. 1. Operations of Mobile IP protocol.

In this following, we briefly investigate the basic operations of standard Mobile IP. There are five main operations in the standard Mobile IP proposals. The five operations are mobile agent discovery, registration, tunneling, binding update, and foreign agent smooth handoffs.

(1) Mobile agent discovery: Mobile agents advertise their presence via agent advertisement messages. MNs determine if they are still linked to the home network using the source IP address in the advertisement message.

(2) Registration: The process by which an MN requests routing services from an FA on a foreign network, informs its HA of its current CoA, renews a registration which is due to expire, and deregisters with the HA when it returns to its home network. The registration process consists of an exchange of a registration request message and a registration reply message between an MN and its HA, possibly involving an FA.

(3) Tunneling: The mechanism by which the HA forwards the packets to the MNs. Using this mechanism, the IP packets are placed within the payload part of new IP packets, and the destination address of the encapsulating IP header is set to the MN's CoA.

(4) Binding update: In the absence of any binding cache entry, the packets destined to an MN will be routed to the MN's home link in the same way that any other IP packet would be, and then will be tunneled to the MN's current CoA by the MN's HA. If the CN had a binding cache entry for the MN, it would be able to send packets directly to the MN without the services of the HA.

(5) Foreign agent smooth handoffs: This operation is useful for defining a smooth handoff mechanism when an MN moves from one foreign network to another. During registration with the new FA, the MN requests the new FA to send a binding update message to the previous FA. This node will then be able to re-tunnel the packets destined to the MN.

2.3 Overview of IP Security (IPSec)

IPSec is a protocol suite defined by the IETF to secure IP packet exchanges [10]. IPSec is designed to provide high-quality, interoperable, cryptographic-based security for IPv4 and IPv6 datagrams through the use of cryptographic key management protocols [2], such as the Internet Key Exchange (IKE) protocol [3]. Two new security headers are defined in IPSec: an authentication header (AH) [6] and an encapsulating security payload (ESP) [7]. The

primary difference between AH and ESP authentication is the extent of coverage. ESP does not authenticate any IP header fields in the outer IP header. AH can provide better integrity check. It protects predictable fields in the outer IP header. In IPSec, AH provides data integrity and authentication using the hashing algorithms Message Digest Algorithm 5 (MD5) and Security Hash Algorithm (SHA-1) [11]. The ESP header provides integrity, authentication, and confidentiality to each IP packet. By using the MD5 and SHA-1 algorithms, ESP provides encryption algorithms like Digital Encryption Standard (DES) and Triple Digital Encryption Standard (3DES) [9].

3 An IPSec-Based Key Management Algorithm

In Mobile IP, there are home and foreign agents running on a wired network. These mobile agents (MAs) periodically broadcast Mobile IP advertisements on wireless networks. Whenever an MN migrates from one subnet to another (foreign) subnet, it starts receiving Mobile IP advertisements from the corresponding foreign agent.

An MN is any type of device that can be attached to the Internet. It can be a wireless laptop, a personal digital assistant (PDA), or an Internet-enabled mobile phone [10]. In the proposed scheme, an IPSec protection model is used to replace the Mobile IP model. IPSec is a standard mechanism for providing secure communications over the Internet [9].

Fig. 2 shows the packet format encrypted with a public key on a wired network. The proposed scheme transfers a packet with an encrypted key and receives a packet with a decrypted key. Hacker most easily invades wired networks. This scheme at each agent all the new IP header of the needle does to encrypt. That can increase and the safety of the packet, but can not increase and made the loading too much.

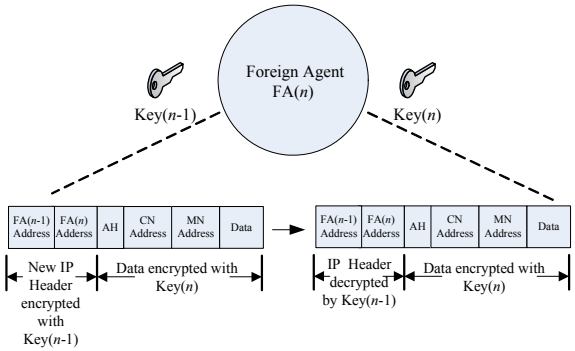

Fig. 2. Packet format encrypted with a public key on the wired network.

As shown in Fig. 3, we use AH to arrive at wireless segment packet security in wireless networks. In the proposed scheme, we describe how we use Key(i-1) of gateway i to decrypt a received packet. Then we use Key(i) of gateway i to encrypt a transferred packet. In the following, we will present the operations on a wired and a wireless network, respectively.

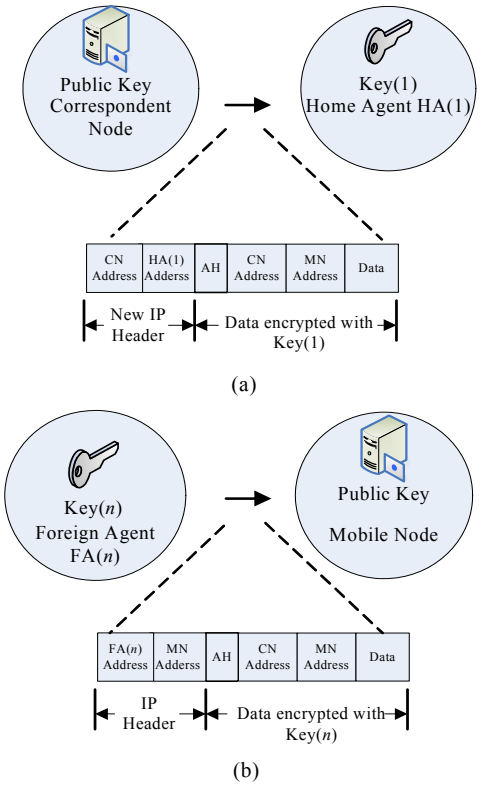

Fig. 3. Packet format encrypted with AH on the wireless network. (a) CN→HA. (b) FA→MN.

3.1 Operations on the Wired Network

In the following, we describe the method of operation of our proposed scheme on a wired network. We will first describe the basic ideas of the routing process and then proceed to describe the data transfer process. We will then describe the data reception process using the IPSec-based security method.

(1) Route Discovery Process

We assume that parameter "n" represents a count of hops from the HA to the FA. To allow for practical deployment requires that we "over-load" existing header fields in a manner that will have minimal impact on existing users. We describe our proposed encoding below. We can adopt any reasonable encoding that comes to light. Fig. 4 shows our choice for using the padding field. Five bits are sufficient to represent 31 hops, which is more than almost all

Internet paths [13]. In the common case, the only modification to the packet is to increment its padding field.

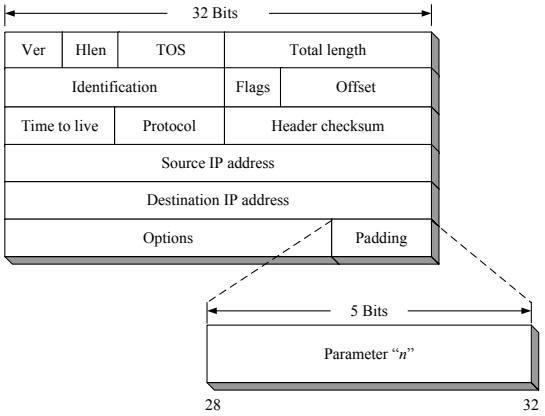

Fig. 4. Encoding parameter "*n*" into the IP padding field.

The route discovery process is described as follows:

Step 1: First, we assume that parameter "*n*" represents the number of hops from the HA to the FA. Parameter "*k*" represents every gateway's number. Each agent stores *k* in each gateway register.

Step 2: The FA produces or obtains a random security key and stores it in Key(*k*). Key(*k*) is used later in the routing process to decrypt a packet. The process will record the parameter "*k*" into the packet.

Step 3: If gateway *k* receives the request message, this means this path has already arrived at the last agent. If gateway *k* does not receive the request message, the routing process stops. The packet will be transmitted to the last agent.

Step 4: When this packet is transferred to the last agent, this packet will store Key(*k*) and Key(*k*-1) to the register of gateway *k*, where *k*>1. When the routing process is finished, every agent (HA or FA) will obtain two keys.

(2) Data Transfer Process

A CN delivers packets to the MN through the HA to FA(*n*). In this case, each mobile agent has two keys: one is Key(*k*) and the other is Key(*k*-1), where *k*>1. Key(*k*) is used to encrypt Mobile IP packets, and Key(*k*-1) is used to decrypt the received packets.

(3) Data Reception Process

Packets are delivered to the HA through FA(*n*). Key(*k*) is used to encrypt the Mobile IP packets, and Key(*k*-1) is used to decrypt the received packets, where *k*>1. For instance, when a packet is delivered to FA(*k*-1), FA(*k*-1) will decrypt the received packets with Key(*k*-1), and use Key(*k*) to encrypt the packets, after which the packets are sent out.

3.2 Operations on the Wireless Network

Wireless network security differs from general computer and network security in that air link is involved, and a wireless network is most concerned with the edges of the network. Good security should be an added feature in existing wireless communication devices. Users that do not need it should not have to pay for it. On the other hand, users that want very secure communication devices should have that option available to them at an acceptable cost. For example, users could be offered the use of compatible but specialized user equipment when better security is needed. This is already being done in some cellular systems for large-scale emergency communications where public safety officials are issued special cell phones that have good interference immunity and priority access to the cell tower.

IPSec provides security by implementing different security algorithms. IPSec adds two specific headers: an authentication header and an encapsulating security payload. The authentication protection in AH does not allow this mode of operation. The AH protocol was designed to improve the security of IP datagrams. The AH protocol provides connectionless integrity, data origin authentication, and an anti-replay protection service. However, AH does not provide any confidential services: it does not encrypt the packets it protects. AH's role is to provide strong cryptographic authentication for IP traffic to ensure that packets that are tampered with will be detected. We show a simple authentication header model for Mobile IP in Fig. 5. The two authentication algorithms in the IP Authentication Header and Encapsulating Security Payload are the HMAC-MD5 and HMAC-SHA-I algorithms [11, 14]. MD5 and SHA-I have many similar characteristics.

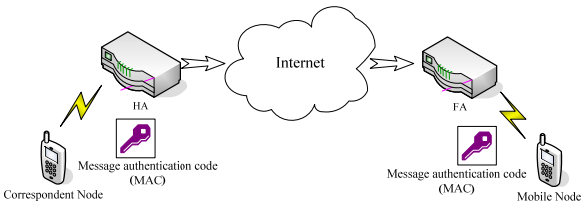

Fig. 5. A simple authentication header model for Mobile IP.

In this case, we use AH to arrive at wireless segment packet security. Fig. 6 shows two methods in which the IPSec authentication services can be used. Fig. 6(a) shows typical IPv4 packets. In this case, the IP payload is a TCP segment; it could also

be a data unit for any other protocol that uses IP, such as UDP or ICMP. For AH transport mode using IPv4, the AH is inserted after the original IP header and before the IP payload (e.g., TCP segment). This is shown in Fig. 6(b). For AH tunnel mode, the entire original IP packet is authenticated, and the AH is inserted between the original IP header and a new outer IP header. This is shown in Fig. 6(c).

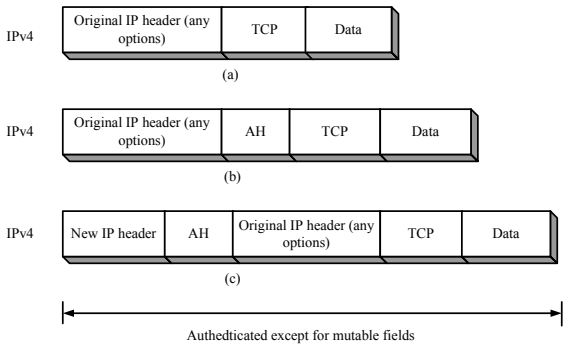

Fig. 6. The Authenticated packet format except for mutable fields after applying AH. (a) Before applying AH. (b) Transfer mode after applying AH. (c) Tunnel mode after applying AH.

4 The Comparisons between IPSec-Based Mobile IP and Traditional Mobile IP

The comparisons of IPSec-based Mobile IP and traditional Mobile IP networks are described as follows.

The IPSec-based Mobile IP networks works on the peer-to-peer mode and the use to operate on MVPN. Oppositely, the traditional Mobile IP networks works on the client/server mode. When it is used to implement MVPN, the compulsory tunnel style must be used and one MVPN device need to implement the access concentrator (AC) function while another need to implement the network server (NS) function. To make them symmetrical, both MVPN devices need to implement AC and NS functions. Obviously, it will increase the implementation overhead and the complexity of configuration and management operations.

Traditional Mobile IP does not provide any security mechanisms or only provides very weak security mechanisms. IPSec-based Mobile IP supports two security protocols: one is the IP authentication header protocol which is used to provide data origin authentication, data integrity, and anti-replay protection; the other is the IP encapsulating security payload which provides data confidentiality, limited traffic flow confidentiality and optional data origin authentication, data integrity, and anti-reply protection. According to the security requirements, they can be used in speared or combined ways. In addition to the security protocols, IPSec also provides complete key management protocols, such as the Internet Key Exchange (ISAKMP/Oakley) protocol.

In an IPSec-based Mobile IP network, when we send a packet from the source to the second security gateway, a hacker can use a private key to unlock the next security gateway's IP address. This means the hacker can know the real address of the next hop. But that does not present a problem since the hacker still does not know what the packet's destination IP address is. In the proposed scheme, each security gateway i (router i) has two keys. One is Key(i) and the other is Key(i-1). When a hacker invades a security gateway, he can only get the Key(i) of that security gateway. The hacker cannot decrypt the received packet. Therefore, the proposed method is safer than the traditional method.

5 Conclusions

With recent advances in wireless communication technology, mobile computing is an increasingly important area of research. End-to-end network security mechanisms, such as IPSec and the rich network services for wireless networks, are fundamentally conflicting mechanisms. In this paper, we proposed a key management algorithm for Mobile IP networks based on IPSec. The proposed scheme includes two parts: a wired network and a wireless network. In the wired network part, the proposed scheme produce two keys in each security gateway, transfers a packet with an encrypted key and receives a packet with a decrypted key. In the wireless network part, we use AH to arrive at wireless segment packet security. By the proposed scheme, we can enhance the security of Mobile IP networks.
