Abstract: - The paper deals with implementation of multiplatform embedded SIP communication server with unified configuration interface which has been developing within the framework of a BESIP project (Bright Embedded Solution for IP Telephony) since May 2011. The BESIP consists of several components which are distributed under GPL as an open-source solution and the whole project is supported by CESNET (Czech Education and Scientific NETwork association). The paper explains and describes the whole concept and individual modules, acquaints with the current state and with the future intents. SIP server is ported into OpenWRT project core and Asterisk with Kamailio inside are used as SIP engines. Kamailio was selected for security and reliability, Asterisk for extensive PBX functions. Next to this, there is implemented Web frontend for user-friendly management. We put emphasis on security, which is ensured by the Security module with IDS/IPS (Intrusion Detection and Protection Systems) and on the Speech quality monitoring with own developed tool. Last, but very important component, is NETCONF server which is part of image and enables an advanced unified management.

Key-Words: - OpenWRT, SIP server, BESIP, Speech quality, VoIP security.

1 Introduction
The BESIP aims to become VoIP PBX system available for anybody, the users need not know complex software features and hidden internals of VoIP software. BESIP offers the prepared solution with integrated key components, the entire system is distributed as an image or individual packages can be installed from SVN and users do not care about dependencies, they just configure VoIP system which works. Every software solution includes own configuration and management. BESIP aims to be scalable solution with security and unified configuration in mind [1]. After research and project discussion we made that decisions:

OpenWRT for good scalability and simple embedding:
- Kamailio for reliability and high availability
- Asterisk and Kamailio as B2BUA (Back-to-Back User Agent) and SIP Proxy
- YUMA as NETCONF server
- OpenWRT UCI as configuration backend

Several open-source applications were adopted and implemented into developed modules, however within the implementation many modifications were required, especially in the core module (OpenWRT) due to complicated porting of applications into OpenWRT buildroot [2]. Our patches were verified and accepted by OpenWRT community. The speech quality monitoring tool was developed from scratch and implemented in Java. BESIP can run on low-end devices with 32MB RAM at least and supports OpenWRT MIPS architecture.

2 Selection of suitable Platform
The most important step which had to be done, was choosing right software distribution/platform. There was an idea to modify Debian distribution, this is probably the easiest way for developers. Debian includes many ports and packages which are available for many software services but Debian is not suitable for embedding. A modification of Debian, in order to be easily embedded into small device with read-only flash, is really a difficult task and the expected results of such work can not lead to a source distribution.

Next solution was adopting some low-level distribution for embedding. There are several possibilities like FreeWrt, OpenWrt, DebWrt etc. After discussion and projects observations, OpenWrt was selected as primary platform. There are many packages included and packages which are
not included and can be added into applications tree. Even if it is not easy procedure for some kind of packages (especially for packages without configure script), we decided for this way. OpenWrt is well-known for great support, ticket system, relatively well documentation and cooperation with community of developers.

3 Architecture and Technology
The BESIP architecture is depicted in Fig. 1, it is created entirely from opensource parts. This was main presumption for project management and developing. There are four basic modules: Core, Security, Monitoring and PBX. Core is divided into following parts:

- OpenWRT as build platform;
- NETCONF For administration of entire system, YUMA implementation was adopted;
- Web GUI for user-friendly configuration;
- SUBVERSION as revision control system providing a support and better orientation for developers, it is not a part of the released BESIP image.

The security module is based on SNORT, SNORTSam and iptables [7]. In addition to this, the Kamailio ratelimit and pike module is used for defending attacks. The monitoring module exploits a tshark package and our java code which interprets its results and gives information about particular speech quality. The Zabbix agent is used to report basic states of entire system and finally the PBX module is made from kamailio in conjunction with Asterisk.

3.1 Configuration Module
The NETCONF protocol exploits a specified mechanism for exchanging the configuration data among an administrator and network devices. This protocol allows the device to send and receive configuration data through XML documents using the RPC paradigm [5]. These XML documents are handed over the RPC calls, the RPC request is initiated by a client that requests the configuration data or a command to be performed on the server. While these requests are being performed, the client is blocked until he receives the RPC reply from NETCONF server [4]. That replies consists of a configuration that is complete or a partial. Another reply is a message informing us if a command was successfully performed on the server or not. This communication is transferred over a transport protocol which has to be secured and to allow an authentification and authorization. Most probable and secure way, how to communicate with the NETCONF server, is to use SSH2 protocol (RPC calls over SSH subsystem).

The structure of configuration data on NETCONF server in YUMA package (netconfd) is specified by the YANG module which defines the semantics and syntax of a management feature. It provides complex data structures which allow design any data structures that will meet the requirements of developers.

Fig. 1. BESIP architecture.

Fig. 2. NETCONF usage.

The configuration data are stored securely on the NETCONF server and all requests and responses must comply with firmly defined structure, specified by YANG modules. Next, global database of all the configurable parameters is required and it is ensured by NETCONF server. The configuration parameters are inserted by the user and stored in the NETCONF server. Consequently, the stored configuration data are available through simple queries. It makes the device quickly configurable, therefore a backup or a restore of configuration can be simply and quickly performed [6].

Yuma is a package which provides tools for the network management. It consists of a NETCONF...
configured by common NETCONF server. Kamailio both engines will work together and will be one of these engines can be configured but in future, includes both Kamailio and Asterisk. Today, only how system will work. From this reason, the BESIP [13]. The BESIP offers users an option to choose difficult to use the advanced PBX functions [8], call routing, more fault tolerant but it is more pure SIP proxy is easier software which can perform is more susceptible to fault. On the opposite side, voice response but due to the bigger complexity, it defined in BESIP.

understand configuration data flow which has been on implementation of NETCONF, UCI, PBX, and libraries had been ported, afterwards we focused on all modules. At first stage of project, applications opened these packages to OpenWrt community yet although we use them. Nevertheless we continue in development of the mentioned packages.

OpenWRT uses UCI as configuration backend, it is a group of configuration files which can be read or modified by common UCI API. We decided to provide a glue between NETCONF and UCI. The long term goal of this project is to make the BESIP configuration independent on clients. Today, many systems are configurable using web, ssh or telnet and each of them offers its own semantics and configuration file. BESIP project aims to change this situation, using NETCONF as defined communication and management protocol, configuration independent syntax will be available on all modules. At first stage of project, applications and libraries had been ported, afterwards we focused on implementation of NETCONF, UCI, PBX, Security and monitoring modules. See Fig. 2 to understand configuration data flow which has been defined in BESIP.

3.2 PBX Module
The PBX module is key part of the BESIP project. It operates as SIP proxy or SIP B2BUA, depending on configuration, and ensures a call routing. Asterisk is used for call manipulation and for the PBX functions. Kamailio is used for the proxying SIP requests, the traffic normalization and for the security [11]. There are always two factors when developing VoIP solution, the first one is high availability and reliability, the second one is an issue of advanced functions. Many developers try to find a compromise, we have implemented both and our BESIP is able to adapt to the users requirements. More complex system can handle many PBX functions such as a call recording or an interactive voice response but due to the bigger complexity, it is more susceptible to fault. On the opposite side, pure SIP proxy is easier software which can perform call routing, more fault tolerant but it is more difficult to use the advanced PBX functions [8], [13]. The BESIP offers users an option to choose how system will work. From this reason, the BESIP includes both Kamailio and Asterisk. Today, only one of these engines can be configured but in future, both engines will work together and will be configured by common NETCONF server. Kamailio will route requests even if Asterisk will be out of order, only advanced PBX functions will be unavailable in such situation [13], [15].

3.2.1 Asterisk GUI
Asterisk-GUI is very flexible web solution of Asterisk management. Even if it is not NETCONF based Asterisk-GUI was added to the first BESIP release. The reason was that at this time, there was not completed an interoperability between NETCONF and Asterisk. It is available in the next release and the implementation involved very complex task. The users can decide to use easy Asterisk-GUI for PBX setup at initial version of BESIP. Nevertheless in future version we would like to remove the Asterisk-GUI package from BESIP image and the configuration will be accessible only through new developed NETCONF based management. During implementation, we solved several technical issues concerning Asterisk-GUI in OpenWRT environment and finally we made a decision on disuse Asterisk-GUI in BESIP roadmap. The last release still links this GUI on the BESIP main page [9].

3.2.2 Accounting
In many systems, an accounting is divided into two separate parts. The individual calls are processed and a call detail record (CDR) is generated to every performed call, these CDRs are stored in text file or a repository. The next part of the accounting is an application which enables to perform statistics over stored data, it means to search and display in accordance with requested criteria. This is a conventional scenario, classical approach of many accounting applications and highly reliable because the PBX function is not affected by accounting and even if there is problem with accounting software, PBX still operates properly. However there is one big disadvantage, during a call setup, the PBX knows nothing about call price and cannot provide an authorization which is well-known from pre-paid services offered by mobile operators. Having this information, we are able to perform more checks and operations at the call setup level. For example, we can look up into user credit and do not permit a call if the credit is depleted or low. Similar to this, we can authorize every call against a threshold, such as maximal price per minute/trunk/global. These thresholds can be pre-set or dynamically changed according to the actual user credit. Having this information, the PBX will be safer and resistant against attacks aimed at an exploitation of the PBX [10].
3.3 Security Module

Security module is very important part of BESIP and all the time, it was considered to make the developed system as secure as possible. Next to this, entire system has to be fault-tolerant, monitored and protected from attacks. It means that if the device is under attack, only attacker has to be blocked, not entire system or other users. If there is some security incident, BESIP immediately solves the situation and notifies this event in detailed report to the administrator. The attack are recognized and processed by SNORT rules, the source IP address is automatically sent into firewall by SNORTSam and the intruder’s IP is blocked. This is very flexible, reliable and effective implementation. Dropping attack based on IP directly in the Linux kernel is much more efficient than to check messages on the application level. Only first messages are going to SNORT filter. When SNORT identifies a suspicious traffic, next messages from the same IP are blocked. In next BESIP releases, we are going to to implement ipqbdb mechanism which will be even more self-defending. It is based on IP denoting.

![Fig. 3. Attack effectivity based on REGISTER flood.](image)

3.4 Monitoring Module

The overall solution of the monitoring system consists of several different open source components and also of the part that was directly developed for this purpose to meet the defined requirements. System structure is depicted in Fig. 5. The system itself consists of three logical components, which are – web interface that serves the administrators (Web GUI), part of the script (Scripts) that controls the obtaining the information necessary to compute the speech quality in the simplified E-model [13]. Last component is part of the Quality Monitor, which contains the logic for calculation itself and performs processing of data obtained by scripts. In the overview SQLite3 database, which is used to store the results.

![Fig. 4. Attack effectivity based on INVITE flood.](image)
The developed application offers the comfort of management in a web application, the developed interface aggregates required functions. Web interface is the main part of user interaction with a monitoring tool. Monitoring tool is turned off in the default configuration and can be enabled using the intuitive main interface of BESIP any time. This part of the monitoring tools is also used as a mean to display the measured and computed results. Structure of the presented data is as follows: Time, Source IP, Destination IP, MOS and used Codec. An example of user interface is shown in Fig. 6.

4 Conclusion
The contribution of our work is entire BESIP concept and its implementation. As we have mentioned, BESIP consists of several components which are distributed under GPL as an open-source solution. A few of them have been fully adopted such as the components in Security and PBX modules, some of them modified, concerning the CORE module and finally we have developed own tool for Speech quality assessment. The contribution of our work is not only few hundreds of hours spent on the development, on the coding BESIP system, we bring a new idea of the unified configuration management, with unified CLI syntax which enables to configure different systems, Asterisk and Kamailio in our case. We perceive that we need to solve a lot of issues, Individual packages are working and after several pre-releases, the version 1.0 was released in November 2011. BESIP is distributed as a functional image for x86 platform but is possible to run it on Vmware or KVM. Configuration is available through web-browser or SSH client. Today, there is a trunk version in SVN which is actively developed and individual improvements are included in next subversions. After testing, version 2.0 will be released, new release 2.0 will be based completely on NETCONF with one API to configure entire system. Next to this, CLI syntax is developed and will be connected to NETCONF. CLI will be independent of internal software so if some internal software is modified, there will be no change in configuration. Even more, CLI and NETCONF configuration will be independent on hardware and version. To export configuration from one box and to import it to the next one will be simple task. Users will modify only one configuration file to manage entire box. After this step, all internals of configuration will be hidden as was mentioned in introduction. Entire BESIP management and development is available at [13] and Binary images from nightly autobild can be downloaded from [14].
