Abstract: The tendency of development of fuel-energy sector of Kazakhstan at the present stage imposes strict requirements for the use of energy sources. In this case the important thing is the development of the "clean" coal combustion with the smallest possible emission of harmful substances, and therefore it is need to optimize all the constructive and operational parameters of the process. The main instrument of the theoretical study of nonlinear heat and mass transfer, and motion of the medium into account the diverse of physical phenomena, such radiative heat transfer, combustion, and other is the mathematical modeling and computer experiment. The mathematical modeling includes not only the development of numerical methods and numerical calculations, but also deep analysis of the model, its adequacy to the real process.

Key-Words: boiler, coal, combustion, concentration, emission, flow, fuel, furnace, heat- and mass transfer, modeling, numerical research, power plant, program complex

1 Introduction

Modern development of heat power engineering is characterized by reduction in the use of scarce of liquid fuels, which is a valuable raw material for the petroleum refining industry and the expansion of application of solid fuels. In the last decade there has been widespread deterioration in the quality of solid fuels, due to the depletion of high-quality coal deposits. Combustion of such low-grade fuels with high ash and moisture content leads to considerable difficulties: worsening inflammation and fuel burn, slagging problems, increases mechanical underburning, increases the emission of harmful dust and gas components (ash, oxides of carbon, nitrogen and sulfur, etc.). In this regard, have developed new methods for reducing emissions by using physical models. The numerical experiment is one of the most economical and convenient way for detailed analysis and deeper understanding of complex physical and chemical processes that occur in the furnaces. Mathematical description of the processes taking place in the steam generators, furnaces and reactors with modern computer algorithms, using computer programs allow to solve problems for specific installations. Combustion of pulverized coal flame in the real world is very complicated for the mathematical analysis of physical and chemical process. The particular complexity of it differs in boiler furnaces, where the axis of the torch is curvilinear, and cold combustion chamber walls shielded cause significant gradient from the periphery to the axis of the flame temperature and all dependent on it physical parameters, which greatly complicates the average temperatures. In this case, even after all possible simplifications have to deal with two or three-dimensional mathematical problem [1]. In modeling the combustion of solid fuel in the furnace uses a variety of different models. In [2] presents the results of the study modes of chemical reactors. Describe the process of making mathematical models of reactors. This contains information on the chemical kinetics and the theory of chemical reactors, which are necessary in the preparation of the mathematical models of industrial power units. In [3] summarized the approximate physical and mathematical model of furnace process, which uses the minimum number of empirical coefficients and dependencies. In [4] justified requirements to develop mathematical models of local combustion of fuel in a diesel engine. In [5], presents the mathematical model heat exchange and combustion
of pulverized coal in the combustion chamber of power boiler, which is based on the model adopted by the non-isothermal incompressible multicomponent gas.

2 Problem Formulation

When considering the heat transfer processes in technical reacting flows in combustion chambers of the heat exchange by radiation makes the largest contribution to the total heat transfer. In the flame zone contribution of radiative heat transfer of up to 90% or more [6]. Therefore, modelling of heat transfer by radiation in the reacting flow in the combustion chambers is one of the most important steps in the calculation of heat exchange processes in real combustion chamber.

In general, at a temperature above absolute zero radiates, absorbs and reflects the electromagnetic waves of different frequencies. These frequencies, which are radiative heat transfer material to be driven by the characteristics of the substance and its temperature. When modeling technical trends in the temperature range 500-2000 K is only meaningful exchange of radiation in the infrared and in the visible region [7]. The mathematical description of radiative heat transfer is generally allocated a region of space in which the fluid moves. The walls of this space and the material contained in it, absorb and emit radiation in the infrared and visible regions.

Quantities’ characterizing the radiation heat transfer is the spectral intensity, which is defined by the following equation:

\[ I_{\nu} = \lim_{\Delta A, \Delta \Omega \to 0} \frac{\Delta E_{\nu, \Theta}}{\Delta A \cdot \Delta \Omega \cdot \cos \Theta} \]

\( \Delta E_{\nu, \Theta} \) - here the radiant energy at a frequency \( \nu \), emitted from the element of area \( \Delta A \), at the solid angle \( \Delta \Omega \), in a direction determined by the cosine of the angle \( \Theta \) (Fig.1).

In emitting, absorbing and scattering environment, the intensity of radiation decreases due to absorption and scattering, and is enhanced by the receipt of the radiant energy from the environment. Scattering is due to both a reflection and a result of diffraction of electromagnetic waves.

Changing in the intensity of the beam of rays is due to the fact that some of the rays changes direction.

Distinguish in the space of an infinitesimal element of length \( ds \). Write the equation of energy balance of radiation. As we take the transport variable intensity of \( I_{\nu} \). In general, this equation is:

\[
\frac{1}{c} \frac{\partial I_{\nu}}{\partial t} + \frac{1}{c} \frac{\partial I_{\nu}}{\partial \nu} = \left( \frac{K_{\text{abs}, \nu} + K_{\text{sca}, \nu}}{I_{\nu}} \right) I_{\nu} + K_{\text{abs}, \nu} \frac{I_{\nu}}{4\pi} \frac{1}{4\pi} \left( I_{\nu} (\Omega_1 \rightarrow \Omega_1) I_{\nu} (\Omega_1) \right) d\Omega_1 (1)
\]

We describe the value of each of the members of the equation above: \( c \) - speed of light,

\[ I_{\nu} - \text{change of intensity over time}; \]

The process of heat transfer by radiation is considered to be quasi-stationary. In addition, as the speed of light is large, the change of intensity over time:

\[
\frac{1}{c} \frac{\partial I_{\nu}}{\partial t} \to 0 \quad (2)
\]

II - intensity distribution along the infinitesimal element \( ds \);

III - reduction of intensity along the element \( ds \), due to the absorption and dispersion of the direction \( \Delta \Omega \) in other directions;

IV - increased of intensity along the element \( ds \), due to its own emission of radiation protection in the direction of \( \Delta \Omega \);

V - Increase of intensity along the element \( ds \), due to the inflow of radiation energy from all directions.

In the balance of radiant energy (1) assumes that came thermodynamic equilibrium. This means that, according to Kirchhoff’s Law, absorption and emission coefficients are equal. We also assume that all the surfaces and volumes involved in the radiant heat transfer are considered gray emitters.

Fig.1 Determination of the spectral intensity
We use the following expression for the calculation of the integrated intensity of the radiation and integrated optical coefficients, which will help to simplify the integral-differential equation (1):

\[ I = \int_{0}^{\infty} I_N d\nu, \]

\[ K_{abs} = \int_{0}^{\infty} K_{abs,\nu} d\nu \]

\[ K_{sca} = \int_{0}^{\infty} K_{sca,\nu} d\nu \]  \hspace{0.5cm} (3)

\( K_{abs} \) and \( K_{sca} \) - optical coefficients of absorption and scattering.

According to Planck's law of black body radiation intensity, we have:

\[ I_b = \int_{0}^{\infty} I_{b,\nu} d\nu = \frac{\sigma}{\pi} T^4 \]  \hspace{0.5cm} (4)

Where \( \sigma = 5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4 \) - Stefan-Boltzmann's constant.

Thus, we obtain the energy transfer radiation equation:

\[ \frac{\partial I_N}{\partial s} = -\left( K_{abs} + K_{sca} \right) I_N + K_{abs} \frac{\sigma}{\pi} T^4 + \]

\[ + \frac{K_{sca}}{4\pi} \int_{\Omega} P \left( \Omega_i \rightarrow \Omega \right) I_N \left( \Omega_i \right) d\Omega_i \]  \hspace{0.5cm} (5)

Change of the intensity of the radiation energy along the element \( ds \) is the sum of its attenuation due to absorption and scattering, gain from its own emissions and increasing the influx of energy from other directions.

Rigorous mathematical description of the processes taking place in the steam generators, furnaces and reactors together with modern computational algorithms using computer programs allow us to solve these problems for specific power plants. Such computing field experiments allow flexibility to intervene in the process of combustion at any stage, and change the design features of the device, practicing individual technical solutions without the high cost.

For the application of mathematical modelling is necessary to have a reasonably accurate and substantial information about the the physical and kinetic parameters, patterns of physical and chemical phenomena in conditions close to real as well.

Solid equipment can have a significant impact on the convective and diffusive transport in streams with high solids content. The presence of solids in the unburned gases from the combustion chamber slightly (except near the burner), and the effect of the second phase of the calculations can be neglected [8] and the combustion of pulverized coal in the combustion chamber can be described as a two-phase flame gas-dispersed system, and the effect of solid phase on aerodynamics for significant [9].

In this model, we take the heat transfer between particles and gas by radiation. The influence of the solid phase to the coefficients of turbulent exchange using the following empirical relationship:

\[ \Gamma_P, \text{ eff} = \frac{\mu_P, \text{ eff}}{\sigma_{P, \text{ turb}}} = \frac{\mu_{\text{ eff}}}{\sigma_{P, \text{ turb}}} \left( 1 + \frac{\rho_P}{\rho_G} \right)^{-\frac{1}{2}} \]  \hspace{0.5cm} (6)

For the turbulent Prandtl-Schmidt numbers considering particles we use the following expression:

\[ \mu_P, \text{ eff} = \mu_{G, \text{ eff}} \left( 1 + \frac{\rho_P}{\rho_G} \right)^{\frac{1}{2}} \]  \hspace{0.5cm} (7)

For the turbulent Prandtl-Schmidt numbers considering particles selected the following numerical values: \( \sigma_{P, \text{ turb}} = 0.7 \).

Share contributed by the gas and solid particles, described by the sum:
Here, to simplify the model of radiation is assumed that the emission band of the two gases completely overlaps, and mass factors and the specific absorption rate depend on the temperature of the gas. Then the absorption coefficient, we have the following relation

\[ K_{abs} = K_{abs,G} + \sum K_{abs,P} k \]  

The values of the mass coefficient and the coefficient of absorption of radiation by water vapor and carbon dioxide used in this study are presented in Table 2.

When modeling the reacting flows, containing substances in the solid phase, it is necessary to take into account that the effect of solid particles on the radiative heat transfer can be several times greater than that of components in the gas phase (water vapor and carbon dioxide). Considering solid phase absorption and emission coefficients can be written as:

\[ K_{abs,P} k = X_{abs} \cdot \tilde{n} P, k \cdot d^2 P, k \cdot \frac{\pi}{4}, \]

\[ K_{Sca,P} k = X_{Sca} \cdot \tilde{n} P, k \cdot d^2 P, k \cdot \frac{\pi}{4}. \]

Where \( \tilde{n} P, k \) - the number of particles in a volume element. Coefficients \( X_{abs} \) and \( X_{Sca} \) are defined experimentally and for the pulverized coal flame has the values: \( X_{abs} = 0.85 \) and \( X_{Sca} = 0.15 \). These values were found for the coefficients of scattering \( a_{Sca} > 30 \):

\[ a_{Sca} = \frac{\pi \cdot d P}{\lambda_{Sca}} \]

The wavelengths correspond to 21 microns of \( dP > 200 \) microns, the average length of a wave up to 3 microns corresponds \( dP > 29 \) microns. Therefore, the ratio is really not for the entire range of particle sizes. According to an error that occurred when receiving the resultant values are neglected. In the radiation model we shall consider only the forward scattering is in good approximation is permissible in pulverized-coal flames. Thus, the scattering does not lead to a weakening of the intensity and subsequently ignored.

### 3 Numerical research

The boiler BKZ-160 Almaty CHP has the \( \Pi \)-shaped profile with a rectangular prismatic combustion chamber (Figure 3), the size of which: 6.565x7.168x21.0 (m³). It is equipped with six boilers, each has a steam capacity of 160 t/h.

Fig.3 Scheme of the boiler BKZ-160

Boilers BKZ-160 manufactured at the Barnaul boiler plant, they have at the bottom of a cold funnel to remove slag, and an individual system for the preparation of coal dust holding bins of two ball mill drum. The burner has a single channel for aero mixture and two channels for the secondary air, the top and bottom of the channel and separated aeromixture lined piers. After each burner comes 3.787 t/h coal dust, and the performance of the boiler as a whole at rated load is 30 t/h. Consumption of secondary air flow through the burner is \( V = 6000 \) nm³/h. At the exit of the burner it has a speed of 40 m/s and temperature 380 °C. Aeromixture temperature at the exit of the burner is 250 °C, and its rate of 25 m/s, so rate of ratio of
secondary and primary air in the burners equal to 1.64, excess air ratio in burners is 0.68, and the output of the furnace is 1.27.

The physical model of the combustion chamber is built in full compliance with the reflecting actual process of burning coal, which is carried out directly in the combustion chamber of the boiler BKZ-160 Almaty CHP. Were set all parameters (fuel, its characteristics, methods and speed of the fuel and oxidant capacity of power plant, the parameters of coal, its composition, temperature of aeromixture, primary, secondary and tertiary air, etc.). This recorded in the built physical and geometrical models of the combustion chamber.

Computational experiments on the combustion chamber of boiler PK.39 were also carried out in [10]. The use of a modern software for the creation of the computational domain is not allowed to apply the restrictions that were imposed on the computational domain in [10]. Creating the database for simulation is carried out in several stages, with the program complex PREPROZ [11]. In the generated files contain geometric data of researched process, the initial and boundary conditions for the simulation of heat and mass transfer in reacting flows. PREPROZ created using basic files containing background information, which are then used in the software package FLOREAN [12, 13]. This computer software package allows for complex computational experiments to simulate reacting multiphase flows in the areas of real geometry.

When creating a geometric model, each wall of the combustion chamber is described separately in the form of numerical codes. First, entered the walls of their corner points. Input and output are set primarily as a type of holes and then are set the coordinates of the spatial position of burners on certain walls. Hole of burner (log) described in the form of concentric circles (for round burners), yield - in a rectangle with the corresponding coordinates in the space. In [10], due to the limitations imposed by creating a geometric model, circular holes were replaced with an equal rectangular area, which also affected the accuracy of the calculations. In accordance with a given geometry of the lattice is created for numerical simulation (Figure 1). In the process of creating the final version of the computational domain, the grid has repeatedly edited in order to create the most optimal variant for further calculations of physical processes in the furnace volume. At our option for lattice computing experiments established the size 27x61x60 which contains 98820 control volumes. In [10] the computational experiments were carried out for 21648 control volumes (estimated grid 16x33x41). The ability to reduce the control volume, especially in the region of the burners allows you to get a more accurate result. In this case, thanks to an improved computer model, by which all numerical experiments were carried out in this thesis, the calculation time increases slightly.

This is the description of the physical model the investigated combustion chamber of the boiler BKZ-160, a common form of and its broken down control volumes for the computational experiments which are presented in Figure 4.
4 Results of modeling

Below shows the results of the 3D modelling of burning of solid fuel (coal) in the combustion chamber.
Fig. 5 (a, b, c, d) - Distribution of U-component of the vector of full speed in different sections of the investigated sections of combustion chamber.

Figure 5 clearly shows the aerodynamic flow pattern of a mixture of pulverized coal flow through the tangential burner.

Analysis of Figures 5 - 7 shows that using tangential flow of pulverized coal mixture in the center section formed vortex flow, causing the fuel burns completely due to a long stay in the maximum temperatures. This in turn reduces the mechanical nedozheg and solves the problem of slagging.

Fig.6 (a, b) - Distribution of V-component of the vector of full speed in the burner section and in upper section of investigated combustion chamber.
In addition, as a result of the computational experiments obtained isosurface distribution of chemical energy, shown in Figure 8.

**Fig. 7** (a, b) - Distribution of W-component of the vector of full speed in the burner section and in the upper section of investigated combustion chamber

**Fig. 8** (a, b) – Isosurfaces of energy distribution of chemical reaction

**Recent Advances in Fluid Mechanics and Heat & Mass Transfer**

ISBN: 978-1-61804-183-8
In Figure 8 clearly seen areas where take place the most intense chemical reaction of combustion. The resulting curves of distribution of the energy released during the flow of the chemical reaction between the fuel (coal) and an oxidant (air), allow us to determine its numerical value at any point in the combustion chamber boiler BKZ-160 Almaty CHP.

4 Conclusion
The results obtained in this work allows to do conclusion that in location area burners has a vortex flow caused by the location of burners and pulverized way of giving vortex flow in the combustion chamber. The presence of the vortex motion provides a more rapid ignition and flame stabilization. Hot gases are swept into the torch, heat the fuel mixture and intensify inflammation. Active ascending currents are also busy area near the walls of the furnace, which in its turn has an impact on the convective component of the heat in the combustion chamber. Amplified Heat and Mass Transfer in a vortex intensifies burnup of coal particles. At the same time can achieve uniform heating of the combustion chamber surfaces and reduce their slagging that extends the hardware. By circulating particles in the vortex torch burning occurs with sufficient fullness, even coarse grind, which can significantly extend the range of use of pulverized coal.
